## PREFACE

2The research contained in this dissertation was completed by the candidate while based in the  
3Discipline of Biology, School of Life Sciences of the College of Agriculture, Engineering and Science,  
4University of KwaZulu-Natal, Westville, South Africa.

5

6The contents of this work have not been submitted in any form to another university and, except  
7where the work of others is acknowledged in the text, the results reported are due to investigations by  
8the candidate under the supervision of Professors Peter Scogings and Himansu Baijnath. .

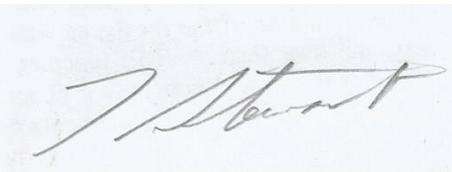

9

10The structure of the dissertation is in the form of papers for publication and therefore necessitates  
11some repetition as well as some variation among the chapters.

**DECLARATION 1: PLAGIARISM**

I, Terry Stewart, declare that:

(i) the research reported in this dissertation, except where otherwise indicated or acknowledged, is my original work;

(ii) this dissertation has not been submitted in full or in part for any degree or examination to any other university;

(iii) this dissertation does not contain other persons' data, pictures, graphs or other information, unless specifically acknowledged as being sourced from other persons;

(iv) this dissertation does not contain other persons' writing, unless specifically acknowledged as being sourced from other researchers. Where other written sources have been quoted, then:

a) their words have been re-written but the general information attributed to them has been referenced;

b) where their exact words have been used, their writing has been placed inside quotation marks, and referenced;

(v) where I have used material for which publications followed, I have indicated in detail my role in the work;

(vi) this dissertation is primarily a collection of material, prepared by myself, published as journal articles or presented as a poster and oral presentations at conferences. In some cases, additional material has been included;

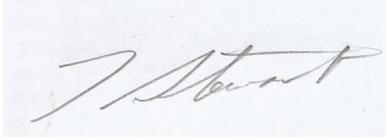

(vii) this dissertation does not contain text, graphics or tables copied and pasted from the Internet, unless specifically acknowledged, and the source being detailed in the dissertation and in the References sections.

**7Chapter 2**

8Stewart T\*, Scogings PF and Baijnath H., An investigation of the encroachment of sub-tropical moist  
9coast grasslands within the urban nature reserves of Ethekewini Municipality by *Dalbergia obovata*, an  
10indigenous forest liana. Submitted to *Bothalia: African Biodiversity and Conservation* on 2<sup>nd</sup>  
11December 2018. The paper presents the results of the analysis of reserve management records and  
12field mapping surveys for the distribution of *D. obovata* in the grasslands of nature reserves within  
13Ethekewini Municipality and concludes that *D. obovata* has encroached into the moist coast grasslands.

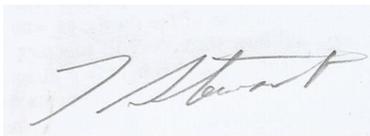

14

**15Chapter 3**

16Stewart T\*, Scogings PF and Baijnath H. An assessment of the distribution of *Dalbergia obovata*  
17diaspores from forest margins and post establishment vegetative propagation within adjacent  
18grasslands. Submitted to *Bothalia: African Biodiversity and Conservation* on 16<sup>th</sup> December 2018.  
19Using a simplified wind dispersal model and analysis of historical changes in distinct stands in  
20grasslands it was concluded that successful establishments were infrequent and that clonal propagation  
21was the primary mechanism for expansion of plants.

**1 ABSTRACT**

2 Encroachment by *Dalbergia obovata* into moist coastal grasslands within eThekweni Municipality was  
3 identified as a potential threat to the conservation of this threatened habitat type. An investigation was  
4 undertaken to confirm whether or not *D. obovata* was in fact encroaching into the city's  
5 grasslands and to identify the probable underlying drivers and local factors that contributed to  
6 encroachment. The investigation comprised four areas of focus. The first was an assessment of the  
7 management practices and records of *D. obovata* encroachment extracted from the available reserve  
8 management records of seventeen nature reserves and conservation areas. The summarised data from  
9 the records was then processed using a Chi-square test and Principal Components Analysis. The  
10 second phase focussed on the application of field surveys to record the distribution patterns of *D.*  
11 *obovata* within four selected management areas. The results were then captured in a GIS map against  
12 which the results of the Chi-square and PCA tests were compared. In phase three a simple theoretical  
13 ballistics model was developed from experimental data to predict the anomochoric distribution of *D.*  
14 *obovata* diaspores from the forest into adjacent grasslands and the critical positioning of parent plants  
15 in the host trees in relation to the edge of the canopy. The final focal area involved the mapping of  
16 individual plants within stands of *D. obovata* and comparison against sixteen years of historical  
17 orthophoto records in order to determine the historic patterns and rates at which *D. obovata* became  
18 established and propagated within the grasslands. During this part of the investigation the vegetative  
19 propagation of *D. obovata* by clonal propagation from lateral branches and roots was identified and  
20 which provided an explanation of how *D. obovata* was able to form large dense stands with no  
21 evidence of canopy contact mortality. The final conclusions were that *D. obovata* parent plants had to  
22 be positioned on the edge of the forest canopy for diaspores to successfully escape the canopy, that  
23 successful establishment of *D. obovata* in grasslands from any particular parent plant was infrequent  
24 and that *D. obovata* did not become established in the presence of large mixed feeder herbivores.  
25 However once established in the grasslands, the ability to spread via clonal propagation enabled *D.*  
26 *obovata* to both outcompete grass species for available resources and be resilient to conventional  
27 bush encroachment management practices which relied on controlled burning programs.

## 1ACKNOWLEDGEMENTS

2The author wishes to acknowledge the following people for their continual encouragement and  
3support. My brother Clive Stewart, my mother Mrs Yvonne Stewart and Mark Hodgetts my life long  
4friend

5

6Gratitude is also extended to the following members of my work colleagues and staff of the Natural  
7Resources management Division of the eThekweni Municipality Parks, Liesure and Cemeteries  
8Department for their assistance with the collection of field data and the provision of management  
9records, Kenneth L Mabila, Philip J Zuma, Nicholas Liebenberg, Thami Kunene, Jabulani Khoza,  
10Christopher Ngcobo and Zethu Gumede. Acknowledgement is also given to the staff of the  
11Environmental Planning and Climate Protection Department of eThekweni Municipality as well as the  
12Reserve Managers and staff of the Scientific Services Department of Ezemvelo KZN Wildlife for  
13access to the reserve management records and nature reserves under their management.

14

15Special acknowledgement is given to Dr D Roberts for her pivotal role in motivating for this research  
16project to be considered for a post graduate study through the Durban Research Action Partnership  
17between Ethekewini Municipality and the University of KwaZulu-Natal and finally to Professor Peter F  
18Scogings and Professor Himansu Baijnath my supervisors at UKZN for their continual guidance and  
19patience during this post graduate research.

## 1 CHAPTER 1: **Introduction**

### 21.1 Rationale for the research

3 The City of Durban (eThekweni Municipality) is situated within the approximate centre of the  
4 Maputuland – Pondoland – Albany biome which is recognised as a global biodiversity hotspot (Boon  
5 et al., 2016). Approximately nine percent or 2267 of the total indigenous plant species for South Africa  
6 (McLean C., 2016) have been recorded within the Municipal boundaries with a large percentage of  
7 them occurring within grassland ecosystems. These grasslands were identified as Kwazulu-Natal  
8 Sandstone Sourveld which is separated by an escarpment at approximately 400m – 450m (Boon,  
9 2017), into an inland region and a coastal belt with a mean annual precipitation (MAP) of 819 mm to  
10 1272 mm (Mucina et al., 2006). These coastal grasslands therefore fall into the category of wet, moist  
11 or mesic grasslands (Devine et al., 2017) which tend to be unstable grasslands (Sankaran et al., 2005)  
12 comprising both grass and woody components, the proportional representation of which is influenced  
13 by a number of local conditions including the frequency and intensity of fires (Govender et al., 2006,  
14 Joubert et al., 2012, Devine et al., 2017). Moist coastal grasslands are also listed as the most  
15 threatened of the South African grassland ecosystems (Cadman et al., 2013) with less than 8% of the  
16 original habitat which occurred within eThekweni Municipality still remaining (McLean C., 2016).

17

### 18 1.2 Justification

19 In 2012, conservation management staff from the Natural Resources Management Division of the  
20 Parks, Leisure and Cemeteries Department, eThekweni Municipality raised concerns regarding the  
21 increased presence of *Dalbergia obovata* (*D. obovata*) in the coastal grasslands. If *D. obovata* was  
22 establishing in grasslands it could, as an indigenous species be considered as an emerging bush  
23 encroachment species. For the purpose of this study, indigenous species bush encroachment is  
24 regarded as having the same outcome as invasion by invasive alien plants in that unless controlled, the  
25 end result is a transition to a near mono species bush or tree cover (Ansley et al., 2006, Archer, 2010)  
26 with a permanent loss of the grassland habitat and its associated indigenous herbaceous species.

27

28

29

### 11.3 Literature review

2 *Dalbergia obovata* is a member of the Fabaceae. *Dalbergia* includes representative species in Africa,  
3 South America, southern and eastern Asia, the tropical Indo-Pacific, Madagascar and Australia.  
4 Relatively little is known about *D. obovata* as a species other than general information describing it as  
5 a climber which uses tendrils, its flowering and fruiting times, and taxonomic information. Unlike  
6 other economically important *Dalbergia* species such as *D. sisoo*, *D. melanoxylon* and *D. nigra*, no  
7 records were found describing the phenology of *D. obovata*. Various gardening websites and work  
8 done at the eThekweni Silverglen Nature Reserve medicinal plant nursery (Nichols, 2017) state that  
9 seeds should be removed from seed pods and scarified in order to germinate but no studies have been  
10 undertaken to determine how that would happen in the natural environment or how the seed dispersal  
11 takes place. Available literature (Coates-Palgrave, 1977, Pooley, 1993), describe *D. obovata* as a liana  
12 or creeper which scrambles through forest canopies and which occurs in coastal and scarp forests and  
13 riverine forests along the Eastern coast of Southern Africa, in low altitude dune forest, swamp forest,  
14 coastal forest, scarp forest, riverine forest and valley thicket (Acocks, 1988, Thomas, 2004) and on the  
15 edges of forests on hill slopes. It is also recorded that it can occur as a tree which attains a maximum  
16 height of 6m both in the wild and as a cultivated shrub and occurs along the Eastern coastal areas of  
17 Sub Saharan Africa from the Eastern Cape to Northern Mozambique or Southern Tanzania from sea  
18 level to an approximate altitude of 900m. During this investigation it was established that *D. obavata*  
19 seeds are small kidney shaped beans averaging 6.5 mm in length and 0.0764 grams in mass. The seed  
20 pods are generally elongated, flattened and tapered at the base and apex with either a single seed  
21 contained at the approximate mid-point or a pair of seeds contained at the 1/3 and 2/3 position along  
22 the length of the seed pod. Single seed pods average 40mm in length and double seed pods average  
23 57mm in length. The width of the pods is a fairly consistent 11mm (Chapter 3) and the general  
24 morphology of the seed pod conforms to that of a wind dispersed winged seed (Greene and Johnson,  
25 1989). No separation of the seed pod and release of the seeds has been observed or recorded and for  
26 the purposes of this investigation it was assumed that the seeds of *D. obovata* are dispersed together  
27 with the pods and are therefore referred to as diaspores. In the absence of detailed information  
28 pertaining to *D. obovata* the general physiology, growth and development characteristics of lianas as a  
29 group are taken into consideration.

Bush encroachment into grasslands, by C3 woody plants is recognised as a worldwide phenomenon (Naito and Cairns, 2011). A full discussion and consideration of the various equilibrium, non-equilibrium and dis-equilibrium models (Gordijn and Ward, 2010), of bush encroachment is beyond the scope of this investigation and is limited to the concepts that are necessary to provide a backdrop against which the investigation of the encroachment of *Dalbergia obovata* into moist coastal grasslands can be discussed. The role of fire, MAP, competition between grasses and woody plants for resources and the contribution of herbivores is covered more extensively in chapter two. The global phenomenon of woody plant expansion into grasslands has been cited as evidence for increased atmospheric CO<sub>2</sub> levels as a global driver of bush encroachment (Wigley et al., 2009) and is supported by evidence available from the global analysis of tree rings which correlates to an increased growth rates of trees in response a global increase in atmospheric CO<sub>2</sub> (Myneni et al., 1997). Investigations into the phase transition of prairie to woodland has indicated that the threshold level at which encroachment becomes self propagating unless the underlying drivers of encroachment are removed is approximately 18% to 20% (Loehle et al., 1996). C3 plant species normally associated with bush encroachment are either trees or shrubs. Typical examples being *Acacia* spp (Bond and Midgley, 2012), *Terminalia* spp, *Dichrostachys cinerea*, *Colophospermum mopane*, (De Klerk, 2004), mangroves (Saintilan and Rodgers, 2015), *Prosopis glandulosa* and *Juniperus* spp (Cabral et al., 2003, Afinowicz, 2004) and *Ulmus pumila* (Su et al., 2015). Literature searches have not identified any cases of bush encroachment by species of lianas.

20

In a parallel phenomenon to the global encroachment of grasslands by woody plants, forests globally have experienced a similar increase in the abundance of lianas (Laurence et al., 2001, Phillips et al., 2002, Gallagher and Leishman, 2012, Yorke et al., 2013). The increased growth rate of lianas in the presence of increased CO<sub>2</sub> (Zotz et al., 2006) has also been cited evidence of CO<sub>2</sub> as a global driver of liana expansion together with local habitat disturbances (Schnitzer and Bongers, 2011, Yorke et al., 2013). Results reported in literature for the estimation of liana population increase in forests vary depending on the methods used with no apparent standardisation of survey methods. Schnitzer and Bongers, (2011), observed a doubling in stem counts and basal stem area whereas Phillips et al.,

1(2002) recorded an increase in canopy cover from 33% to 75% of the canopy area where previous  
2studies on the distribution of lianas estimate that lianas comprise up to 33% of tropical forests.  
3Assessments of liana distribution within tropical forests (Yorke et al., 2013) indicated there is a  
4negative correlation between the frequency of liana stems and basal stem diameter in relation to  
5distance from the edge of the forest, with a decrease in the number of plants in response to an  
6increased distance from the edge (Laurence et al., 2001). Conversely the average basal stem diameter  
7increased with distance from the edge of the forest. This was confirmed by Londré and Schnitzer,  
8(2006) who concluded that there was a marked decrease in liana density towards the centre of forests.  
9It is suggested that this spatial pattern of lianas within forests is in response to habitat fragmentation as  
10opposed to elevated CO<sub>2</sub> or climate change and that lianas appear to benefit from habitat  
11fragmentation and associated increases in forest edges (Londré and Schnitzer, 2006, Arroyo-Rodríguez  
12and Toledo-Aceves, 2009). Schnitzer and Bongers, (2011) cited four methods of propagation utilised  
13by lianas to cover gaps in the forest canopy; (i) seed dispersal and germination, (ii) advanced  
14regeneration of damaged stems, (iii) lateral growth of branches along the forest floor with rooting and  
15generation of vertical growth and (iv) long distance clonal recruitment via vines in the canopy which  
16fall to the ground and then root.

17

18Although there are parallels between encroachment of woody plants into grasslands and the increase  
19of lianas in forests there are also significant differences in that with the exception of *Toxicodendron*  
20*diversifolia* in North America which can occur as shrubs of 3.8 – 4m high (Badel et al., 2015) and  
21*Secamore sparsiflora* in Madagascar, (Lahaye et al., 2005), no references were found pertaining to  
22liana species which had encroached into grassland habitats outside of forests.

23

24The evolution of lianas has resulted in significant modifications in the mechanical and hydraulic  
25characteristics of liana trunks (Lahaye et al., 2005). In self-supporting plants, the stems or trunks have  
26to resist axial compression as a result of gravity and the crown weight (Badel et al., 2015) and a  
27combination of stiffness and flexibility to resist lateral bending or breaking as a result of wind or loads  
28due to the mass of ice, snow or fruit. Lianas or non-self-supporting climbers (Rowe and Speck, 2005,  
29Gianoli, 2011) have a growth advantage over self-supporting plants in that they are able to achieve

1  
2

1vertical growth and large areas of leaf surface by using other plants for support without having to  
2invest energy and biomass in the building of support trunks to support the weight of branches and  
3leaves and resist dynamic loading (Rowe and Speck, 2005, Isnard and Silk, 2009). Lianas are  
4therefore able to invest in supernumerary or secondary cambium tissue (Isnard and Silk, 2009) which  
5allows for an increased hydraulic capacity in relation to stem diameter. Where the above ground  
6portions of lianas may only be 5% of a forests biomass, the leaf area may actually comprise 33% of  
7the canopy allowing for a high ratio of leaf weight and surface area to xylem. Yorke et al., (2013),  
8reported that the branches of large lianas can extend in a radius of up to 500m from their main stem or  
9trunk. The reduced carbon investment and nutrient requirements required for the growth of flexible  
10stems combined with the increased hydraulic capacity per unit measure of stem diameter and  
11increased leaf area to biomass ratio therefore gives lianas a competitive advantage over self-supporting  
12trees in forests (Schnitzer and Bongers, 2011).

13

14Analysis of the genome size in regard to the evolution of *Dalbergia* (Hiremath and Nagasampige,  
152004) found that climbing members of the genus have a significantly higher genome content  
16indicating that *Dalbergia* climbers evolved from tree like forms via a process of acquiring extra genes.  
17Investigation into the developmental growth patterns of *Secamore sparsiflora* (Lehaye et al., 2005)  
18suggests that it achieves a shrub like form via the addition of genes to partially suppress the transition  
19from stiff juvenile stems to compliant and flexible adult stems with the growth of anomalous cambium  
20tissue. The self-supporting phase observed in climbers such as *Toxicodendron diversifolia* and  
21*Bauhinia guyanensis* (Rowe and Speck, 2005) is limited to the juvenile phase of growth which may be  
22extended until the plant comes into contact with a host and that the evolution of the climbing growth  
23form may limit reversion to a fully self-supporting growth form. The implication is that unless lianas  
24are able to attach to a host plant and complete their development, they remain in a state of immaturity.

25

#### 261.4 Key research questions

27Three key questions were identified regarding the encroachment of grasslands by *D. obovata*.

281.4.1 Is there substantive evidence that *D. obovata* is actually encroaching into the grasslands or are  
29 changes in its distribution attributed to changes in forest boundaries and woody vegetation cover

3

1  
2

1 as a result of reserve management practices?

21.4.2 What are the wind dispersal patterns of *D. obovata* diaspores and is there a critical position that  
3 the parent plant must occupy on the host trees canopy in order for diaspores to escape the forest's  
4 boundary?

51.4.3 How does *D. obovata* grow and propagate once it becomes established in the grassland?

6

7A subsequent question that was raised as a result of field surveys of *D. obovata* distribution in the  
8grasslands, was the identification and mapping of large dense stands of *D. obovata* which appeared to  
9show no evidence of canopy contact mortality and excluded all other plant species within the area  
10covered by the stands canopy. If this was the case then how was *D. obovata* able to avoid the  $^{-2}/3$   
11Power Rule of self thinning?

12

### 131.5 Predictions

14It was predicted that the encroachment of *D. obovata* into the moist coast grasslands would not be  
15ascribed to a single factor or driver but that it will be shown to be a combination of global drivers and  
16local factors such as the growth and development characteristics of climbers which provide lianas a  
17competitive advantages within forests, seed dispersal characteristics, global drivers of bush  
18encroachments and local factors such as habitat fragmentation, veld management practices and fire  
19regimes.

20

### 211.6 Aims and objectives of Chapter 2 and Chapter 3

22The aim of chapter two was to undertake an analysis of the available management records of  
23seventeen nature reserves and conservation areas within the eThekweni Municipal boundaries in  
24conjunction with field surveys and mapping exercises of the distribution of *D. obovata* undertaken in  
25four of the management areas. The objective of these was the confirmation of whether or not *D.*  
26*obovata* had encroached into the coastal grasslands. In Chapter three, the overall aim was to  
27investigate the methods of the dispersal of diaspores beyond the edge of forests and the patterns  
28vegetative propagation or reproduction of *D. obovata* once established in the grasslands. Two  
29objectives were identified for chapter three. In the first, a simplistic theoretical wind dispersal model

3

1 was developed in order to test the relationship between the positioning of *D. obovata* in the canopy of  
2 host trees and the successful dispersal of diaspores beyond the forest's edge. The second objective was  
3 to map the exact positions of individual plants within established stands in the grasslands and their  
4 interconnecting root systems in order to determine the rates at which the stands expanded over time  
5 and confirmation of clonal propagation as a method of vegetative reproduction by *D. obovata*.

6

7 The final discussions of the results from chapters two and three are considered in the context of the  
8 physiology and other attributes of lianas together with the possible effects of global drivers of  
9 encroachment presented in chapter one.

142.1 Abstract

The encroachment of a forest liana, *Dalbergia obovata*, into moist coast grasslands within urban nature reserves in eThekweni Municipality was identified as a concern by reserve management . Any encroachment by woody plants has the potential to reduce the viability of the remaining patches of this threatened habitat with a resulting loss of biodiversity. *D. obovata* has not previously been recorded as an encroacher species in grasslands. An analysis of the available management records and status of *D. obovata* in seventeen urban nature reserves and conservation areas was undertaken. A field survey of the general distribution patterns of *D. obovata* was also undertaken to verify the accuracy of the analysis of the management records and the results were captured as layers on a Geographic Information System (GIS). The results of the Chi-square test and Principal Components Analysis together with the final GIS based maps confirmed that in the absence of large herbivores *D. obovata* was not effectively controlled through historic bush encroachment management practices. *D. obovata* could no longer be considered as occurring in only forest or woodland habitats but has successfully encroached into the moist coast grasslands of the reserves of eThekweni Municipality and represents a further threat to this already threatened grassland habitat.

## 12.2 Introduction

3The City of Durban (eThekweni Municipality) is situated within the Maputland – Pondoland –  
4Albany biome biodiversity hotspot (Boon et al., 2016). According to McLean, (2016), 2267  
5indigenous plant species or approximately nine percent of the total indigenous plant species list for  
6South Africa have been recorded within the cities boundaries. A significant percentage of these plants  
7occur within the remaining grasslands. These grasslands largely comprise Kwazulu-Natal Sandstone  
8Sourveld which is separated into two sub types by an escarpment at approximately 400m – 450m  
9(Boon, 2017). Thus there is a drier inland region which is more typical of KZN Sandstone Sourveld  
10and a coastal belt with a higher mean annual precipitation (MAP) of 819 mm to 1272 mm (Mucina et  
11al., 2006) which falls into the category of wet, moist or mesic grasslands (Devine et al., 2017). These  
12mesic grasslands tend to be unstable in composition (Sankaran et al., 2005) and comprise complexes  
13of grass and woody species the proportions of which are influenced by local conditions such as the  
14frequency and intensity of fires (Govender et al., 2006, Joubert et al., 2012, Devine et al., 2017). Moist  
15coast grassland are also listed as the most threatened of the South African grassland ecosystems  
16(Cadman et al., 2013). Less than 8% of the original grasslands which occurred within eThekweni  
17Municipality are left (McLean, 2016). A number of threats to these remaining grasslands have been  
18identified and include invasion by invasive alien plant species (IAPs) (Richardson and van Wilgen,  
192004), change in land use from undeveloped open space to developed transformed land (Rouget et al.,  
202016), land invasion by informal settlements (Pithouse, 2016) and bush encroachment (Cadman et al.,  
202013).

21

22For the purpose of grassland management the uncontrolled encroachment of grasslands by indigenous  
23woody species is regarded as having the same outcome as invasion by IAPs in that unless  
24encroachment is controlled, the end result is a transition to a near monospecific vegetation cover with  
25permanent loss of the grassland habitat and its associated indigenous herbaceous species (Ansley et  
26al., 2006). In 2012 *D. obovata* was identified by managers of nature reserves within eThekweni  
27Municipality as having an increased abundance within the coastal grasslands. Encroachment by *D.*  
28*obovata* into grasslands within the city or Kwazulu Natal was not found in any of the available  
29literature or management records.

Bush encroachment, is recognised as a worldwide phenomenon (Naito and Cairns, 2011). 'Walters Two Layer model' (Walter and Mueller-Dombois, 1971) provided a model of tree - grass relationships in dry savanna based on the principle of 'vertical niche separation'. In this model the rooting depth of adult trees and grasses is identified as occurring in two distinct layers. Since grass species tend to have shallower but denser root systems they are able to efficiently exploit available upper soil water from limited rainfall. Conversely, adult trees have deeper roots and are able to access the deeper ground water. However tree seedlings with their shallower root systems have to compete directly with the grasses for available water in the upper soil layer. Vertical niche separation has been used to identify overgrazing as a driver of bush encroachment in dry savanna and rangelands (Ansley et al., 2006 , Ward, 2010) where removal of grass cover results in greater availability of water for tree seedlings that are then recruited into the adult population. In grasslands that receive more than 650 mm MAP, water is more readily available and is not a factor limiting maximum tree coverage (Devine et al., 2017) and the limiting resources are nutrients and light (Riginos., 2009, Moustakas et al., 2013). In grasslands with an annual rainfall exceeding 650mm MAP threshold, suppression of bush encroachment is related to the fire returns frequency, fire intensity and the susceptibility of tree seedlings to grassland fires (Higgins et al., 2000, Bock et al., 2007). This, in conjunction with competition from grasses for resources, prevents recruitment of the seedlings into the population of adult trees.

19

State and transition models (Stringham et al., 2003, Meyer et al., 2007, Johanson, 2011), provide a working platform for the interpretation of tree – grass dynamics and bush encroachment in moist or humid grasslands where the proportional influence of global drivers such as increased atmospheric CO<sub>2</sub> or temperature, and/or local factors such grazing intensity in combination with competition for resources such as water and nutrients, the impact of fire regimes or shifts in annual rainfall may cause the shift of an ecosystem from one state to another. These potential changes in ecosystem states may include shifts from grasslands to savanna, from savanna to forest or the converse. State and transition models also assume that since there is a dynamic response of habitats to environmental conditions there is an implication that bush encroachment is a naturally 'self' reversible condition if the drivers of

1

2

1 encroachment are removed and local factors are manipulated by land management practices. Reversal  
2 of encroachment does not however automatically restore the herbaceous species that were lost as a  
3 result of bush encroachment (Ansley et al., 2006), especially if the bush encroachment coincides with  
4 habitat fragmentation and IAP invasion (Archer and Predick, 2014).

5

6 The global phenomenon of woody plant expansion into grasslands has been cited as evidence for a  
7 global driver of bush encroachment (Wigley et al., 2009). Further evidence in support of CO<sub>2</sub> as a  
8 global driver of bush encroachment has been provided by the analysis of tree rings which have shown  
9 a correlation between increased growth rates of trees and the global increase in atmospheric CO<sub>2</sub>  
10 (Battipaglia et al., 2013). C<sub>3</sub> trees growing under conditions of elevated CO<sub>2</sub> are therefore able to  
11 increase the allocation of carbon storage to their roots (Curtis and Wang, 1998) which allows for an  
12 increased availability of stored resources for the regeneration of photosynthetic capacity after fires, an  
13 increased post burn recovery rate (Bond and Midgley, 2012) and an increased recruitment of tree  
14 seedlings into the adult population. Studies undertaken in Ithala Game Reserve (Gordijn and Ward,  
15 2010) and the Hluhluwe-iMfolozi Game Reserve (Case and Staver, 2017) have also shown that veld  
16 fires conducted at historic frequencies as per the nature reserve's veld management programs, are no  
17 longer controlling bush encroachment.

18

19 *Dalbergia obovata* is described as a liana in the Fabaceae family which occurs along the eastern  
20 coastal areas of sub-Saharan Africa from the eastern Cape to northern Mozambique and southern  
21 Tanzania from sea level to an approximate altitude of 900m. It has been recorded in several forest  
22 habitats including dune forest, swamp forest, coastal forest, scarp forest, riverine forest and valley  
23 thicket (Coates Palgrave, 1977, Pooley, 1993) and on the edges of forests on hill slopes where it may  
24 occur as a tree or shrub up to 6m in height. There is however no mention by any authors of the plant  
25 being considered as a grassland species and relatively little is known about *D. obovata* as a species  
26 other than general information describing it as a climber which uses tendrils, its flowering and fruiting  
27 times, and taxonomic information. The species is described as flowering from October to November  
28 and that the mature winged flattened seed pods ripen from February to March.

29

3

1 In a parallel phenomenon to the global encroachment of grasslands by woody plants, forests globally  
2 are experiencing a similar increase in the abundance of lianas (Schnitzer and Bongers, 2011., Yorke et  
3 al., 2013). However, with the exception of a limited number of examples, such as *Toxicodendron di-*  
4 *versifolia* in North America which can occur as shrubs of 3.8 – 4m high and *Secamone sparsiflora* in  
5 Madagascar (Lahaye et al., 2005), there is very little references in literature to liana species that occur  
6 outside of a forest habitat.

7

8 The question that therefore needs to be answered is whether or not *D. obovata* is actually actively en-  
9 croaching into the grasslands. On the assumption that, because *D. obovata* is a forest liana, it's distri-  
10 bution is determined by changes in forest boundaries, it was hypothesised that *D. obovata* in grass-  
11 lands was a passive result of management practises aimed at controlling encroachment by other woody  
12 species e.g., grassland burning and mechanical and chemical bush control. In order to confirm this a  
13 twofold approach was taken. The first step was an analysis of the reserve management records from  
14 seventeen nature reserves and conservation areas within the Ethekewini Municipality. The results of  
15 this were then 'ground truthed' by selecting four nature reserves for field surveys.

16

### 17 2.3 Methods

#### 18 2.3.1 Analysis of Management practices and records of *D. obovata* encroachment

19 From the available Durban Metropolitan Open Space Systems (D'MOSS) layer of Ethekewini  
20 Municipal Geographic Information Systems (GIS) database, ten nature reserves and seven  
21 conservation areas containing either moist coast grasslands or KZN Sandstone sourveld were selected  
22 between an altitude of 50m above sea level and 600m above sea level. One nature reserve was divided  
23 into four management areas on the basis of each area being distinctly separated from the other areas  
24 and having different management programs. This then provided a total of twenty study areas  
25 (Appendix 1).

26

27 The management records for each study area were obtained and data extracted regarding the historic  
28 frequency of veld fires, whether or not the fires were planned or unplanned, the season in which burns  
29 occurred, the intensity of fires as indicated by the use of head fires versus back fires, the use of fire-

1  
2

1 breaks around forest margins as opposed to allowing fires to burn into the forest margins, the presence  
2 of IAPs and IAP clearing programs, woody plant encroachment into the grasslands and  
3 implementation of bush encroachment control programs, the presence of large herbivores, (either bulk  
4 grazers or mixed feeders) and whether or not encroachment into the grasslands by *D. obovata* had  
5 been recorded by the reserve managers.

6

7 The summarised results of the extracted data were captured in an XL table with management  
8 components entered as the independent variables and recorded encroachment by *D. obovata* as the  
9 dependant variable. Recorded encroachment was assigned score of 1 and an absence of *D. obovata*  
10 was recorded as 0. Scores were as nominal values or categorical data. The strength of the relationship  
11 between management practices and *D. obovata* encroachment was analysed by performing a Pearsons  
12 Chi- Square test and a Principal Components Analysis. The Chi-square and PCA tests were run with  
13 management variables entered as fourteen individual components. For the PCA test only the  
14 coefficient scores pertaining to the correlation between the management components and  
15 encroachment by *D. obovata* as the dependent variable were considered as this was the relationship  
16 being tested for.

17

### 18 2.3.2 Field surveys of *D. obovata* distribution and mapping of individual stands of *D. obovata*

19 From the results of the management practices versus *D. obovata* encroachment analysis, three reserves  
20 and one conservation area were chosen for a ground level survey of *D. obovata* distribution patterns.  
21 The field survey area were selected on the basis of being below the altitude of 350m which placed  
22 them well below the transition zone of coastal grasslands to KZN sandstone sourveld and that they  
23 also had well documented management histories. This was done in conjunction with the analysis of  
24 the available orthophotos of the survey areas which were provided by the Ethekewini Land Survey  
25 department for the years 1999 to 2016. Since *D. obovata* is deciduous the lack of foliage during the  
26 dry season prevents accurate identification of the plant amongst other vegetation. Surveys were  
27 therefore restricted to the growing season from September to late February when flowering and  
28 production of seed pods also occurred. This aided the identification of *D. obovata* plants in the forest  
29 canopies. Due to the absence of previous surveys of *D. obovata* there was no existing data base

3

1 against which comparisons of previous mapping exercises of the spread and densities could be made.  
2 Conventional methods used to estimate the infestation rate of IAPs or encroachment of woody plants  
3 rely on the ratio of stem counts per sample area, percentage canopy cover of the sample area and the  
4 height of plants using representative numbers of quadrats or line transects which are then extrapolated  
5 to the entire survey area (Elzinga et al., 1998). The use of percentage canopy cover is useful for large  
6 moribund stands of plants but lacks accuracy when estimating the density of seedlings or the number  
7 of plant stems and the use of stem counts requires the removal of the canopy cover which becomes  
8 labour intensive. A minimum representative sampling of five percent of the grassland cover visible in  
9 the 1999 orthophotos, using five random 100m<sup>2</sup> quadrats per hectare for a total of 190.43ha of  
10 grassland to be surveyed across four nature reserves would have required 950 quadrats. The estimated  
11 time required to undertake this was calculated at 2190 hours and made conventional sampling using  
12 quadrats or line transects infeasible for this survey.

13

14 Remote surveys based on the analysis of aerial photos and satellite images have been used  
15 successfully to survey large areas with the use of quadrats or transect sampling to confirm the  
16 accuracy of the remote survey results thereby reducing the time and labour component required for  
17 conventional surveys (Kotzé et al., 2010). It has however been noted that high resolution aerial photos  
18 of less than 10m resolution are required for accurate identification of trees and shrubs (Forsyth, 2012).  
19 The rambling growth form of *D. obovata* results in branches growing through the canopies of other  
20 vegetation as well as the similarity of the plant to other indigenous grassland woody species in its  
21 early growth stages was considered as a confounding factor in remote sensing. This was exacerbated  
22 by a lack in consistency in the time of year in which the aerial surveys from which the aerial photos  
23 used in this study were flown by the Ethekewini survey department. Since *D. obovata* loses its leaves  
24 during the dry season it cannot be detected among other vegetation using analysis of aerial photos  
25 taken during the winter. The common approach noted in available literature in bush encroachment and  
26 IAP infestation surveys was to either record the presence or absence of IAPs or woody encroachers, or  
27 to focus on the degree of infestation based on stem or canopy cover ratios to the surface area of the  
28 land being surveyed. No literature was found which set a threshold value based on which an area was  
29 considered encroached or not encroached. The assessment method used for the annual field

1 assessment and management of IAPs within the Ethekeweni Municipal Nature Reserves was therefore  
2 adopted and applied. In this method simplified categories of woody plant to grass ratios were used aid  
3 with the visual assessment of large areas of vegetation. These categories were 1:1m<sup>2</sup> – 1:4m<sup>2</sup>, 1:4m<sup>2</sup> –  
4 1:16m<sup>2</sup>, 1:16m<sup>2</sup> – 1:64m<sup>2</sup>, 1:64m<sup>2</sup> – 1:400m<sup>2</sup>, 1:400m<sup>2</sup>m<sup>2</sup> – 1:2500m<sup>2</sup> and less than 1:2500m<sup>2</sup> and  
5 where a ratio of IAP's to indigenous vegetation of 1:64m<sup>2</sup> was considered to be invaded. The  
6 estimation of *D. obovata* densities was therefore based on the ratio of *D. obovata* plants to a given  
7 area of grassland or a visible portion of *D. obovata* per area of forest canopy and a ratio greater than  
8 1:64m<sup>2</sup> or 6.5% was considered to be encroached. Prior to the commencement of the field survey the  
9 method was calibrated by setting up a series of 4m x4m test plots along a transect in Marian Wood  
10 nature Reserve starting from the edge of the forest and running 100m into the grassland over an area  
11 encroached by *D. obovata*. This permitted the use of a laser range finder and maps overlaid with a ten  
12 metre by ten metre grid to estimate the distribution of *D. obovata* plants. The results were captured as  
13 layers on a GIS project which allowed comparison of changes in the grassland and woody vegetation  
14 cover from 1999 to 2015 against the occurrence of *D. obovata* recorded during the survey.

15

16

## 17 2.4 Results

### 18 2.4.1 Results of the analysis of Reserve Management practices and recorded *D. obovata* encroachment

19 Mixed results were obtained from the records of *D. obovata* encroachment and reserve management  
20 practices with ten of the management areas or 45% of the grasslands recorded as having been  
21 encroached by *D. obovata* and eleven of the management areas or 55% as having no encroachment  
22 (Appendix 2). The Pearson's Chi Square tests (Appendix 3) indicated a significant association  
23 ( $P < 0.05$ ) between the absence of large mammalian herbivores in the grasslands and *D. obovata*  
24 encroachment. There were no significant associations between *D. obovata* encroachment and other  
25 management practices, such as the season, frequency and intensity of fires, the occurrence of  
26 encroachment by other woody species, or the control of IAPs ( $P > 0.05$ ).

27

28 The results obtained from the PCA identified four axis which accounted for 82.29% of the total  
29 variance (Appendix 4). The first axis (Appendix 4), accounted for 39.46% of the variance, the second

1  
2

1 for 17.07% , the third was 16.42% and the fourth axis accounted for 9.33% of the variance. The scores  
2 obtained from the correlation matrix (Appendix 5) gave a correlation of -0.522 for both bulk grazers  
3 and mixed feeders, -0.369 for head fires and 0.369 for back fires. Only the correlation of management  
4 variables to encroachment by *D. obovata* (Appendix 5), were considered as this was the relationship  
5 being tested for. Other correlation scores between the management variables were therefore  
6 disregarded. The remaining components had correlations lower than 0.30. This indicated that bulk  
7 grazers and mixed feeders (large herbivores) accounted for the greatest proportion of the variance and  
8 was best correlated to the first two principle components identified by the eigenvalues.

9

10

#### 11 12.4.2 Results of the distribution mapping of *D. obovata* within four survey sites

12 The mapped distributions of *D. obovata* within the four selected survey sites at New Germany Nature  
13 Reserve, Roosefontein Nature Reserve, Palmiet Nature Reserve and the UKZN Westville Campus are  
14 presented in Appendices. 7 to 10 and show that *D. obovata* was not uniformly distributed but occurred  
15 in patterns of densities ranging from a maximum density of 1:1m<sup>2</sup> to a minimum of  $\geq 1:2500\text{m}^2$ . The  
16 extent of the grassland area which had been encroached by *D. obovata* when compared against the  
17 1999 orthophotos is presented in Appendix 6.

18

19 In New Germany Nature Reserve the four management blocks (Appendix 7) had different levels and  
20 patterns of encroachment. Approximately 4724m<sup>2</sup> or 5.2% of the available grasslands in Block 1 had  
21 been encroached by *D. obovata* where it occurred in bands of short stunted plants within the fire  
22 breaks on the boundary of forests and along road verges with some isolated stands within the  
23 grasslands. In Block 2, *D. obovata* was restricted to the edges of the bush clumps. In the combined  
24 management blocks of 4&5, the grassland loss to bush encroachment was calculated at 3381m<sup>2</sup> or 2.81  
25 % with no observed encroachment of *D. obovata*. Blocks 4&5 were identified from the reserve  
26 management records as being one of the areas that had mixed feeders, all of which had no *D. obovata*  
27 encroachment. Block 3 was recorded as the only management area where programs of brush clearing  
28 and controlled burns have resulted in a significant increase in grassland cover of 35644m<sup>2</sup> or 91%.  
29 However a total of 58119m<sup>2</sup> or 76.53% of the grassland in Block 3 was encroached by *D. obovata*.

3

1  
2  
1

2The total *D. obovata* distribution patterns for Roosefontein Nature Reserve (Appendix. 8) records that  
3193034m<sup>2</sup> or approximately 8% of the reserve has very high *D. obovata* densities of 1:1m<sup>2</sup> – 1:4m<sup>2</sup>  
4which were located either along the edges of roads or on the North East facing slopes on the western  
5boundary of Merrivale North and Merrivale South management blocks. Appendices 11 – 14 provide  
6photographic examples of these distribution patterns within the reserves. Of particular note was a  
7stand in the main Roosefontein block (Appendix 14), of approximately 20011m<sup>2</sup> in extent which is  
8almost 100% *D. obovata*. A further 1090164m<sup>2</sup> or 45% of the combined reserve area has *D. obovata*  
9densities of 1:4m<sup>2</sup> – 1:64m<sup>2</sup>. A further 576171m<sup>2</sup> or 24% of the reserve has *D. obovata* densities of  
101:64m<sup>2</sup> – 1:400m<sup>2</sup> which are restricted to areas of forest. The remaining 540370m<sup>2</sup> or 22.52% of the  
11reserve comprises grasslands with *D. obovata* densities of less than 1:400m<sup>2</sup> – 1:2500m<sup>2</sup>.

12

13The vegetation of Palmiet Nature Reserve is 98.9% scarp forest and riverine forest with two small  
14fragmented grasslands on the Dawncrest and Faurea ridges amounting to a total of 2754m<sup>2</sup>. The  
15combined grassland cover showed a net increase of 7.5%. Patches of medium to high density stands  
16of *D. obovata* were recorded on the borders of the grasslands and between groups of trees on the  
17fringes of the forest (Appendix 9) and which displayed the same growth patterns as the plants  
18observed within the fire break areas of New Germany Nature Reserve.

19

20The UKZN Westville campus had the highest rate of grassland loss to bush encroachment and IAPs  
21(Appendix 10). Of the original 362827m<sup>2</sup> of grassland visible on the 1999 orthophotos only 204069m<sup>2</sup>  
22or 56.24% remained at the time of the survey representing a 63.27% loss over an eight year period  
23through a combination of bush encroachment, development of road infrastructure and land invasion by  
24the adjacent informal settlement. The recorded patterns of *D. obovata* encroachment in the original  
25grassland areas and remaining eastern grasslands were similar to those observed in the other three  
26nature reserves. Where all of the M19 hillside grasslands have been lost through bush encroachment  
27and IAP invasion, medium to high levels of *D. obovata* encroachment of approximately 1:16m<sup>2</sup> –  
281:400m<sup>2</sup> were recorded. Approximately 43% of the eastern grassland area had medium to high density  
29*D. obovata* encroachments of 1:4m<sup>2</sup> – 1:64m<sup>2</sup> which occurred along the edges of the grasslands

3

1 adjacent to roads, the bottom of watercourses and areas which were previously grassland. Less than  
2 260% of the area was estimated to have a medium to low density of 1:64m<sup>2</sup> – 1:2500m<sup>2</sup>. The highest  
3 levels of *D. obovata* encroachment of 1:1m<sup>2</sup> – 1:4m<sup>2</sup> and were restricted to a narrow band alongside  
4 the road verges and parking lots adjacent to the Palmiet Valley.

5

6

## 7 2.5 Discussion

8 The results of the analysis of the management records and ground level surveys were unexpected since  
9 *D. obovata* is a forest liana and the assumption was that its distribution would be determined by the  
10 contraction or expansion of its preferred forest habitat. Expansion of *D. obovata* into grasslands was  
11 therefore expected to coincide with certain management practices aimed at controlling bush  
12 encroachment.

13

14 The Chi-square and PCA test results only indicate the strength of associations and relationships  
15 between components and variables but don't explain causality. With regard to the influence of fire  
16 frequency, fire season, and fire intensity the available literature indicates that an increase in fire  
17 frequency should suppress bush encroachment (Sankaran et al., 2008, Gordijn and Ward, 2010, Case  
18 and Staver, 2017). Therefore if changes in *D. obovata* distribution are in response to changes in forest  
19 and woodland cover then increased fire frequency should be associated with a corresponding decrease  
20 in *D. obovata* distribution as would burning in late winter of early spring, and the use of head fires  
21 (Govender et al., 2006, Bock et al., 2007). However in the management area block No.3 of New  
22 Germany Nature Reserve (Appendix 7), significant encroachment by *D. obovata* has occurred despite  
23 an increase in grassland cover and a decrease in bush encroachment by other woody species. From the  
24 summary of reserve management practices (Appendix 2) it was noted that this reduction of general  
25 woody encroachment was achieved in conjunction with the application of fire management programs  
26 where head fires were used in early spring and allowed to burn into the bush clumps. This indicated  
27 that woody encroachment by species other than *D. obovata* can be achieved through correctly planned  
28 burning programs (Higgins et al., 2000, Bock et al., 2007) . By contrast the low correlation matrix  
29 scores obtained from the PCA tests (Appendix 5) for the use of head fires, back burns and and

3

1 frequency of fires, AIP and bush encroachment control and the use of fire-breaks indicated very weak  
2 correlations between conventional bush encroachment management practices and the prevention of  
3 encroachment by *D. obovata*. The weak positive correlation associated with the use of head fires may  
4 however explain the pattern of short stunted *D. obovata* plants observed on the borders of forests and  
5 within fire-breaks where controlled burning is implemented. Although the fire does not prevent the  
6 spread of *D. obovata*, it may keep them trapped within the top kill zone as Gullivers (Higgins et al.,  
7 2000). Conversely, the correlation matrix recorded a negative correlation between the presence of  
8 large herbivores in the grasslands and encroachment by *D. obovata*. The PCA results thus confirm the  
9 Chi-square results which found no relationship between any of the management practices but  
10 established that there is a relationship between the absence of bulk grazers and mixed feeders and  
11 encroachment of the grasslands by *D. obovata*.

12

13 It is generally accepted that mixed feeders and grazers are associated with the removal of grasses  
14 which compete with woody plants for nutrients and light (D'Onofrio et al., 2015) thereby allowing  
15 woody plant seedlings to establish themselves more successfully. However the reserve management  
16 records (Appendix 2), show that in all instances where mixed feeders and bulk grazers were present in  
17 a reserve or a management block of a reserve no encroachment of *D. obovata* into that particular  
18 grassland had occurred. This was supported by the field surveys (Appendixes 6 to 10) where no  
19 encroachment by *D. obovata* was recorded in blocks 4&5 at New Germany Nature Reserve where  
20 mixed feeder herbivores were present. Similar patterns of suppression of woody encroachment by  
21 large herbivores have been recorded in Australia (Maher et al., 2010), Northern China (Su et al., 2015)  
22 and East Africa (Sankaran et al., 2013) where exclusion of large herbivores resulted in the subsequent  
23 increased encroachment of grasslands by woody plants. Investigation of the role of large herbivores in  
24 "Rewilding" projects in the Netherlands (Cornelissen et al., 2014) demonstrated that bulk grazers and  
25 mixed feeders can reduce bush encroachment by specific plant species such as *Sambucus nigra* and  
26 *Salix* spp and promote the establishment of grasses and other herbaceous species. Cattle and horses  
27 have similar dietary patterns to wildebeest, and zebra whereas deer species have similar diets to  
28 impala and free ranging domestic goats (Gebert and Verheyden-Tixier, 2001, Dunham, 1982, Raats,  
29 1998). Thus, although overgrazing by large herbivores is normally associated with bush encroachment

3

1  
2

It may be also be effective in the reduction of specific woody species in grasslands.

2

3In the ground level surveys *D. obovata* was recorded as being present in all of the grasslands surveyed  
4where large herbivores were absent (Appendixes 6 to 10) and tended to occur in distinct patterns of  
5high density bands on the edges of forests and bush clumps and decreased with increasing distance  
6from the forest-grassland boundaries towards the centre of the grasslands where small isolated stands  
7and low density scatterings of plants in grasslands occurred. Although the mechanisms and patterns of  
8propagation and diaspores dispersal of *D. obovata* did not form part of this investigation, the pattern of  
9decreasing plant densities relative to the forest borders indicates that encroachment into the grasslands  
10by *D. obovata* is a progressive linear process. The dense stands of 100% *D. obovata* covering several  
11hectares in extent (Appendixes 9 and 14) and smaller stands of *D. obovata* recorded in the grasslands  
12of the survey areas (Appendix 14) indicate that encroachment by *D. obovata* results in the complete  
13exclusion of other indigenous species. This does not conform to bush encroachment where an  
14ecosystem shift occurs from grassland habitat to woodland or forest habitat (Stringham et al.,2003,  
15Johanson, 2011) but is more analogous with mono species IAP invasions (Ansley et al., 2006, Archer,  
162010) with a corresponding loss of biodiversity. Although the threshold level for classifying an area as  
17encroached was set at a ratio  $\geq 1:64\text{m}^2$ , *D. obovata* plants were recorded as being established at lower  
18densities in all of the study areas except for management blocks 4&5 at New Germany Nature Reserve  
19and the implication being that encroachment had already started wherever large herbivores were  
20absent.

21

22

### 232.6 Conclusion

24In consideration of the presentation of evidence in available literature for the influence of global  
25drivers such as increased CO<sub>2</sub> and mean annual temperature which have resulted in the increased  
26growth rates of woody plants and liana species in particular and in the absence of any previous  
27literature citing forest liana species as encroaching into grasslands it was expected that the expansion  
28or contraction of *D. obovata* populations in moist coast grasslands would correlate with general bush  
29encroachment. It was also expected that any expansion of *D. obovata* within the grasslands would

3

1 therefore be a result of management practices which promote or suppress bush encroachment. The  
2 results of the analysis of management practices compared to encroachment by *D. obovata* and the  
3 results of the field surveys have shown that traditional bush encroachment management practises  
4 based on historical grassland burning regimes have not prevented the encroachment of *D. obovata* into  
5 the moist coast grasslands within the study areas. The results of the ground level surveys have also  
6 shown that the historical assumption that *D. obovata* is restricted to forests and woodland habitats is  
7 no longer correct and that *D. obovata* has successfully encroached into the grasslands outside of the  
8 forest habitat. A relationship between the absence of large herbivores in the grasslands of the study  
9 areas and the encroachment of *D. obovata* in moist coast grasslands was also identified although the  
10 mechanisms are not currently understood. It is therefore concluded that in the absence of large  
11 herbivores, *D. obovata* has become a bush encroachment species within the moist coast grasslands  
12 with the capacity to permanently transform this threatened habitat into mono species stands with a  
13 corresponding loss of biodiversity.

#### 16 2.7 Acknowledgements

17 The author wishes to acknowledge the following contributors without whom this research would not  
18 have been possible. The staff and work colleagues of the Natural Resources Management Division of  
19 the Parks, Leisure and Cemeteries Department and Environmental Planning and Climate Protection  
20 Department of Ethekewini Municipality as well as the Reserve Managers and staff of the Scientific  
21 Services Department of Ezemvelo KZN Wildlife for access to the reserve management records and  
22 nature reserves under their management. Dr D Roberts for her pivotal role in motivating for this  
23 research project to be considered for a post graduate study through the Durban Research Action  
24 Partnership between Ethekewini Municipality and the University of KwaZulu-Natal.

123.1 Abstract

Encroachment into the moist coast grasslands within Ethekewini Municipality by *Dalbergia obovata*, an indigenous species of forest liana which formed dense mono species stands that excluded all other plant species and did not appear to undergo self-thinning, was identified as a potential biodiversity threat. Identification of the mechanisms of *D. obovata* diaspore dispersal from neighbouring adjacent forests and subsequent patterns of propagation within the grasslands was required to understand how *D. obovata* encroached into the grasslands. A simple wind dispersal model for *D. obovata* diaspores was developed and compared against the historic orthophoto records of two nature reserves. Field surveys were also undertaken to map the distribution of plants within stands of *D. obovata* in the grasslands of the study areas and to investigate the primary methods of propagation by *D. obovata* once it had become established. The results of the wind dispersal modelling and field surveys showed that *D. obovata* dispersal was a product of the height of host trees and wind velocity but for successful dispersal to occur *D. obovata* had to occupy a position close to the forest margin. Successful establishments of *D. obovata* were infrequent but a resistance to grassland fires and clonal propagation from the roots and lateral branches resulted in a constant expansion of the stands and accounted for the lack of evidence of self-thinning. The progressive expansion of the stands in the grasslands was confirmed as representing a threat to the grasslands.

13.2 Introduction

2Encroachment of grasslands by woody plants has been reported globally (Naito and Cairns, 2011) and has  
3been attributed to a combination of universal drivers such as an increase in atmospheric CO<sub>2</sub> (Wigley et al.,  
42009) and local conditions (Devine et al., 2017, Joubert et al., 2012) such as mean annual precipitation,  
5overgrazing and veld management practices. A similar global increase in the occurrence of lianas in forest  
6canopies has also been recorded (Laurence et al., 2011, Philips et al., 2002, Gallagher and Leishman, 2012,  
7Yorke et al., 2013). As with woody species associated with encroachment of of grasslands, the increased  
8growth rate of liana growth and expansion has been attributed to the global increase of CO<sub>2</sub> (Zotz et al.,  
92006)), together with local habitat disturbances (Schnitzer and Bongers, 2011, Yorke et al., 2013) which have  
10provided opportunities for lianas to take advantage of increased forest margins. Estimation of liana  
11population increases in forests have varied according to the methods used. (Schnitzer and Bongers, 2011),  
12recorded a doubling in stem counts and basal stem area with an associated increase in biomass, whereas  
13other researchers such as Philips et al (2002), recorded increases in canopy cover from 33% to 75% of the  
14canopy area.

15

16Studies on the distribution of lianas within the Amazonian forest estimated that lianas comprised up to 33%  
17of tropical forests (Yorke et al., 2013) but that there is a relationship between the frequency of liana stems  
18and basal area relative to the increased distance inwards from the edge of the forest (Laurence et al., 2001),  
19with a decrease in the number of plants in response to an increased distance. Conversely the average basal  
20stem diameter of increased with distance inward from the forest edge and plant age. This was confirmed by  
21Londré and Schnitzer (2006), who also concluded that there was a marked decrease in liana density towards  
22the centre of forests. It is suggested that these spatial patterns of lianas within forests were also in response to  
23habitat fragmentation and increased forest margins as opposed to elevated CO<sub>2</sub> or climate change and that  
24lianas appear to benefit from habitat fragmentation and the associated increase in forest edges (Londré and  
25Schnitzer, 2006, Arroyo-Rodríguez and Toledo-Aceves, 2009).

26

27Schnitzer and Bongers (2011), cited four methods of propagation utilised by lianas to cover gaps in the forest  
28canopy; (i) seed dispersal and germination, (ii) advanced regeneration of damaged stems, (iii) lateral growth  
29of branches along the forest floor with rooting and generation of vertical growth and (iv) long distance clonal

1  
2 recruitment via vines in the canopy which fall to the ground and then take root. Yorke et al (2013),  
3 confirmed that a large percentage of liana recruitment in old forest areas that was disturbed by logging  
4 operations was via long distance clonal colonisation, specifically from the re-rooting of fallen vines and that  
5 large lianas can extend in a radius of up to 500m from their main stem or trunk. Available literature (Coates  
6 Palgrave, 1977, Pooley, 1993), describes *D. obovata* as a liana or creeper which scrambles through forest  
7 canopies but which can also occur as a tree that attains a maximum height of 6m both in the wild or as a  
8 cultivated shrub. The analysis of the reserve management practices and records of *D. obovata* encroachment  
9 into the grasslands from seventeen conservation areas within the eThekweni Municipal area were confirmed  
10 by detailed ground level surveys which showed that *D. obovata* was encroaching into the grasslands with up  
11 to 43% of the grassland in some reserves having been encroached (Stewart et al., submitted). *D. obovata* is  
12 capable of forming dense mono species stands within grasslands with stands covering up to 2 ha in extent  
13 (Stewart et al., submitted). The threshold level at which encroachment becomes self-propagating unless the  
14 underlying drivers of encroachment are removed is approximately 18% to 20% (Loehle et al., 1996) and if  
15 *D. obovata* is establishing in grasslands it could be considered as an emerging bush encroachment species.

16 The process of self-thinning or Yoda's  $^{-3/2}$  power rule, is widely accepted as a general law and describes the  
17 process of natural plant mortality and reduction of plant densities in response to canopy contact mortality and  
18 competition for resources (Zeide, 1987, Wiegand et al., 2008) and has been shown to operate consistently  
19 across a wide range of conditions (Reynolds and Ford, 2005) from high density stands of short lived annuals  
20 such as *Impatiens capensis* to long lived *Pseudotsuga menziesii* where self-thinning occurs between the ages  
21 of 800 and 1200 years. Although this study did not investigate the application of the self-thinning law to the  
22 growth and propagation of *D. obovata* it was noted that no evidence of canopy contact mortality was  
23 observed in either the field surveys or the historic orthophotos.

24  
25 Relatively little is known about *D. obovata* as a species other than general information which describes it as  
26 a climber that uses tendrils, its flowering and fruiting times, and taxonomic information however the detailed  
27 phenology of *D. obovata* in terms of its complete life cycle including its reproductive strategies is largely  
28 unknown. Anecdotal evidence (Nichols, 2017) suggests that seeds first need to be removed from the seed  
29 pods and scarified, and that fresh seed needs to be used in order for successful germination in a nursery

1  
2  
3environment nursery. No studies have been undertaken to determine scarification is required in the natural  
4environment, what the possible agents responsible for scarification would be or even how the seed dispersal  
5takes place.

6  
7The survival and spatial distribution of organisms with a sessile adult phase of their life cycle depends on  
8having mobile seeds, spores, eggs or larvae (Pergl et al., 2011). It then follows that the spatial dynamics  
9(Levin et al., 2003) and the long term survival of any plant species depends on the probability of their seeds  
10or other reproductive tissues (Klein, 1999, Vivian-Smith et al., 2007), reaching a suitable medium for  
11germination or growth and subsequent recruitment of seedlings into the adult population (Greene and  
12Johnson., 1989, Levin et al., 2013).

2  
3Secondary dispersal may also account for the final dispersal patterns of seeds (Schurr et al., 2005) through  
4accidental dispersal by species which predate on seeds such as insects and rodents (Forget and Milnerton,  
51991, Milesi and Lopez De Casenave., 2004., Wall, 2008). Seed removal does not however automatically  
6equate to seed predation or consumption (Vander Wall et al., 2005). Elaiosome-bearing seeds use ants as

1 vectors (myrmecochory) for seed dispersal (Whitney, 2002), but examples also exist of fungus farming ants  
2 harvesting seed pods of non-myrmecochoric tree species with the removal of seeds from the pods inside the  
3 ant nests (Milesi and Lopez De Casenave, 2004). The evolution of fungus farming in new world ants  
4 (Meuller et al., 2001), is paralleled by the evolution of fungus farming termites in Africa and Asia (Aanen  
5 and Boomsa, 2006, Aanen and Eggleton, 2005), but no records were found of secondary dispersal through  
6 seed pod harvesting by termites.

8 In order for *D. obovata* to successfully encroach into grasslands from adjacent forests or bush clumps the  
9 diaspores must be successfully distributed beyond the forest boundary and once germinated, plants must be  
10 capable of successfully expanding and competing with grass species for resources such as water, nutrients  
11 and light (Riginos., 2009, Moustakas et al., 2013). Three questions were therefore raised concerning *D.*  
12 *obovata* distribution and propagation: (1) how far are *D. obovata* diaspores carried by wind into the  
13 grasslands, (2) is there a critical position that the parent plant must occupy on the host tree's canopy in order  
14 for diaspores to escape the forest boundary, (3) how does *D. obovata* grow and propagate once established in  
15 the grassland.

### 18 3.3 Methods

19 Two approaches were employed to investigate the dispersal of diaspores beyond the boundaries forests  
20 adjacent land and the subsequent expansion of stands of *D. obovata*. The first method was the development  
21 of a simplified ballistics chart for the dispersal of diaspores under different wind strengths and its application  
22 to positions on the host plant's canopy. The second method entailed the mapping of plants within *D. obovata*  
23 stands in grasslands and the analysis of historical ortho photos as well as the investigation of any evidence of  
24 vegetative propagation.

#### 26 3.3.1 Diaspore Dispersal

27 Analysis of the terminal velocities of diaspores and predicted wind drift in regard to distance from the  
28 canopy edge

29 Two alternative methods were considered for the modelling of wind dispersal of *D. obovata* diaspores. These

1 were the direct observation method and ballistics modelling. The direct observation of seed dispersal and  
2 mapping of seed dispersal is done by either observing the flight of seeds in the field or recording the number  
3 and location of seeds found in the field in reference to a known parent plant or by using seed traps placed in  
4 specific patterns of direction and distance from a known seed source (Bullock and Clarke., 2000, Nathan et  
5 al., 2002). Most seeds tend to fall within short distances of the parent plant with long distance seed dispersal  
6 generally considered as distances over 100m (Cain et al., 2000) but becomes increasingly less accurate as  
7 distance increases, (Levin et al., 2003). “Non-buoyant particles of different materials like seeds and fruit  
8 supported by aerodynamic forces always move relative to the air when in flight”, (Burrows 1975, page 405).  
9 During free-fall in still air, all objects will experience gravitational acceleration until the force exerted by  
10 gravity is balance by the upward pressure of the air as a result of aerodynamic drag and a steady terminal  
11 velocity is reached. The aerodynamic drag is a product of the objects velocity, density, cross sectional surface  
12 area and the air density or wind pressure constant (Burrows 1975). The same principal can be applied to the  
13 lateral acceleration of seeds until the horizontal wind velocity is reached. Indirectly it means that the drag  
14 can be calculated for an object of a known mass in free fall in air by comparing the point at which terminal  
15 velocity is reached with the theoretical velocity of the same object in a vacuum. Once the drag is known the  
16 effective aerial buoyancy and volume can be calculated.

18 Simple ballistics models used for the calculation of single projectile trajectories consider the launch angle,  
19 muzzle velocity, ballistic coefficient, drag and gravitational attraction (Jauhari, 1986). Indirect methods of  
20 predicting seed or diaspore dispersal tend to be mechanistic models which integrate ballistics formulas with  
21 statistical components to describe patterns of seed dispersal under varied conditions or phenomenological  
22 models which describe seed dispersal and can be incorporated into mechanistic models (Levin et al., 2003).  
23 The simplest of these models describing anemochoric dispersal of seeds are based on ballistics formulas with  
24 the most important variables being horizontal wind speed, the release height of seeds and terminal velocity of  
25 the seeds (Marion and Ohanian, 1979, Burrows, 1975, Greene and Johnson, 1989). More precise modelling  
26 requires the inclusion of wind turbulence, vortex shedding and storm events (Cain et al., 2000, Nathan et al.,  
27 2002, Soons., et al., 2004, Tackenberg et al., 2003), which can greatly extend the range of seed dispersal. The  
28 inclusion of statistical calculations is required when dealing with multiple seeds which exhibit a degree of

1  
2 randomness resulting from a combination of variables such as individual release heights, variances in dia-  
3 spore morphology, wind speed and turbulence (Cain et al., 2000, Nathan et al., 2002, Soons., et al., 2004,  
4 Tackenberg et al., 2003).

5 In the case of *D. obovata* however, there are no records of the mass release of diaspores from parent plants or  
6 corresponding recovery of diaspores from the field. This necessitated the use of a simplified ballistics model  
7 for the calculation of the theoretical flight path of the diaspores. Most models of seed dispersal assume an  
8 instantaneous horizontal wind velocity and terminal velocity (Soons., et al., 2004, Tackenberg et al., 2003)  
9 and is convenient when calculating seed dispersal over long distance when released from tall trees. This  
10 assumption could however introduce inaccuracies when considering that the release heights of diaspores  
11 from a parent plant above the host tree canopy may be measured in centimetres and determination of the  
12 distance of the parent plant inward from the canopy which may be critical to the successful dispersal of  
13 diaspores beyond the forest margin.

14  
15 Mature, dried *D. obovata* diaspores were collected at random from trees adjacent to survey site 1C at Marian  
16 Wood Nature Reserve of which one hundred selected at random and then measured, weighed and dropped  
17 individually from a height of 4.5m in a still air environment against a graduated backdrop. The backdrop was  
18 marked in vertical increments of 0.25m and the diaspores descent was filmed using a Fuji Film S4300 14  
19 mega pixel camera with a 35mm wide angle lens at 30 frames per second. The videos were then analysed  
20 using Adobe Premier PRO CC 2015.5 which allowed the flight times of the diaspores to be viewed at 10%  
21 speed at 308.7 frames per second in sequentially numbered frames. The results were captured into a  
22 spreadsheet which allowed the frames per height increment to be converted to  $\text{ms}^{-1}$  and the average initial  
23 rates of vertical acceleration, the point at which average terminal velocities were attained and other ballistics  
24 data to be calculated by entering the formulas into the spreadsheet. The difference between the terminal  
25 velocity and the theoretical velocity in a vacuum for the same height and the wind pressure constant was  
26 used to calculate the average cross sectional area of the diaspores in flight. This was then used to calculate  
27 the average rate of horizontal acceleration during free fall under different theoretical wind strengths and the  
28 corresponding time and distance travelled before wind speed was reached and the average angle of descent.  
29 Microsoft PowerPoint 97/2000 XP was then used overlay the final diaspore trajectories under varying

1 theoretical wind speeds over a background grid drawn on a photo of a tree with a rounded crown shape that  
2 was growing in the grassland at Marian Wood Nature Reserve and which was covered with *D. obovata* and  
3 mature *D. obovata* diaspores.

4

5 The standard equations of motion, force and pressure used for the ballistics calculation were;

$$6 \quad \mathbf{V} = \mathbf{U} + \mathbf{s} / \mathbf{t} \quad (3.3.1.1)$$

$$7 \quad \mathbf{s} = \mathbf{ut} + \frac{1}{2} \mathbf{at}^2 \quad (3.3.1.2)$$

$$8 \quad \mathbf{V}^2 = \mathbf{U}^2 + 2\mathbf{as} \quad (3.3.1.3)$$

$$9. \quad \mathbf{V}_{(0.25m)} = \mathbf{S} / \mathbf{t}_{(0.25m)} = \mathbf{S} / (\sum(\mathbf{fr} / \mathbf{frs}^{-1}) / \mathbf{n}) = 0.25 / \sum(\mathbf{fr} / 308) / 100 \quad (3.3.1.4)$$

$$10 \text{ and } \mathbf{a}_{(0.25m)} = \Delta \mathbf{V}_{(0.25m)} / \mathbf{t}_{(0.25m)} = (\mathbf{V} - \mathbf{U}) / \mathbf{t} \quad (3.3.1.5)$$

$$11 \quad \mathbf{P} = \mathbf{F}/\mathbf{A} = (\mathbf{m} \times \mathbf{a})/\mathbf{A} \quad (3.3.1.6)$$

$$12 \quad \mathbf{V}_d = (\mathbf{V} - \mathbf{U}) / \mathbf{t} = (\mathbf{Pw} \times \mathbf{A}) / \mathbf{m} \quad (3.3.1.7)$$

$$13 \text{ where } \text{Horizontal displacement} = \mathbf{V}_d \times \mathbf{t}_{(h)} \quad (3.3.1.8)$$

$$14 \text{ and the angle of decent is } = \mathbf{tan}^{-1} (\mathbf{s}_{(h)} / \mathbf{s}_{(w)}) \quad (3.3.1.9)$$

15 Where  $\mathbf{V}$  = final velocity

16  $\mathbf{U}$  = initial velocity

17  $\mathbf{s}$  = distance

18  $\mathbf{t}$  = time

19  $\mathbf{V}_{(0.25m)}$  = average diaspore velocity per 0.25m vertical height increment in =  $\text{ms}^{-1}$

20  $\Delta \mathbf{V}_{(0.25m)}$  = difference in velocity between 0.25m height increments =  $\text{ms}^{-1}$

### 9 Testing for secondary seed dispersal of *D. obovata* diaspores.

10 A set of six wire mesh baskets was set out at Marian Wood nature Reserve at site 1C. Two baskets were  
 11 placed 5m inside the edge of the forest, two baskets were placed among the vegetation in the forest/grassland  
 12 ecotone and remaining two baskets were placed 5m into the grassland. A total of one hundred dried *D.*  
 13 *obovata* diaspores were placed in each basket to prevent them from being blown away by the wind and  
 14 inspections and counts of the diaspores in each basket was done on a weekly basis for the months of January  
 15 2017 to June 2017. If diaspores had been removed from the baskets it was recorded and the number topped  
 16 up and monitored.

17

### 18 3.3.2. Mapping of individual stands of *D. obovata* and comparison against historic GIS data

19 Field mapping exercises were undertaken of stands of *D. obovata* in three grasslands within two nature  
 20 reserves that were identified from available reserve management records and preliminary surveys of *D.*  
 21 *obovata* encroachment (Stewart et al., submitted). Two of these were at Marian Wood Nature Reserve and  
 22 the third at the Treasure Beach Grasslands Reserve.

23

24 Marian Wood Nature Reserve

25 Survey site 1C, (29° 50' 116.9" S, 30° 50' 29.1" E), was located in a small but species rich portion of  
 26 grassland on the top of a hill and survey site 2A (29° 50' 19.7" S, 30° 50' 27.4" E), was located in a low lying  
 27 grassland in a valley bottom.

3

The two survey grids were set up in March 2012 to cover all visible *D. obovata* plants in the stands. A 60m x 240m grid was set up at survey site 1C and a 30m x 30m grid at site 2A. Due to the smaller size of the *D. obovata* stand at site 2A a smaller survey grid was adequate. Permanent concrete posts were placed on the corners of the 20m grids as reference points for follow up surveys. The canopy was removed in order to expose the stems for accurate mapping. All of the stems were cut 10cm above the ground and a herbicide was applied after which stainless steel tags were attached for future identification. This was done in order to allow differentiation in follow up surveys between original mapped plants which may have regrown and new seedlings. The tagged stems were then mapped in 1.0m x 1.0m squares and captured onto a GIS map. The sites were resurveyed in June 2015 and again in September 2016 to check the accuracy of the tagged plants to be used as reference points for comparison of the available historic ortho photos from 1999 to 2016. A second survey was then undertaken at site 1C and 2A in October 2016 to establish if *D. obovata* used clonal propagation from the roots. This entailed the excavation and mapping of the course interconnecting roots of all plants that were tagged during the first survey. Monthly site inspections were continued until September 2018 and any new seedlings were mapped as a new layer on the GIS project using the available 2016 backdrop. The accurate mapping of all plants from all surveys and capturing as individual layers per survey allowed for the positions of all surveyed plants to be superimposed onto the visible stands of *D. obovata* in the historical orthophotos and enabled the year in which stands were first established to be identified, the rates of expansion until they were treated with herbicide and identification of any new plants that became established after the initial herbicide application. The most probable parent plants were also identified by mapping the predominant wind directions at each site and identification of any mature *D. obovata* plants in the forest canopy relative to the *D. obovata* stands along the prevailing wind lines. On completion of the field surveys the stems of the potential parent plants at site 1C which were identified along the prevailing wind lines were cut and treated with 5% picloram in order to prevent further encroachments. The parent plant at site 2A was not cut and treated initially because the host tree was broken during a storm leaving only the trunk with the main stem of the *D. obovata* vine still attached. This plant subsequently regenerated and was then cut and treated during a follow up survey in June 2015.

Treasure Beach Grasslands Reserve (29° 56' 39.25" S, 30° 59' 53.00" E).

An initial survey was conducted in September 2016 at the Treasure Beach grassland where the perimeters of

1  
2  
3two distinct stands of small *D. obovata* seedlings were recorded and against which any subsequent expansion  
4could then be measured. The grasslands were re-surveyed in September 2018 to assess the spread of  
5*Dalbergia obovata*. During the second survey other indigenous woody encroaching species were also  
6included to provide input into the review of the reserve management plans.

7  
8Two permanent concrete survey posts were placed along the North - South axis through the centre of the  
9grassland in line with a survey beacon. A permanent boardwalk on the perimeter of the grassland was also  
10measured off and marked at 10m intervals as reference points. The approximate boundaries of the stands of  
11encroaching species were marked with poles and a series of fixed point photographs were taken from the  
12survey posts. The boundaries of the encroaching species and position of individual plants were recorded  
13relative to the survey posts and boardwalk and the results captured as a GIS layer against the available 2016  
14backdrop. The distribution of *D. obovata* was then compared with the distribution recorded two years  
15previously.

14

15

### 163.4 Results

#### 173.4.1. Diaspore dispersal

##### 18Analysis of the terminal velocities of diaspores and resulting wind drift

19Analysis of the videos of diaspores dropped against a backdrop marked off in 0.25m increments established  
20that the initial rate of acceleration reached a maximum of  $5.77\text{ms}^{-2}$  at 0.25m of fall and then decreased until  
21the terminal velocity of  $1.95\text{ms}^{-1}$  was reached at approximately 1.0m of fall (Appendix 2). This corresponded  
22to the average distance at which diaspores either began to rotate along their axis, spun in a helical manner or  
23did both at the same time. This behaviour was erratic with diaspores displaying a range of motion ranging  
24from the helical spiralling of non-rotating diaspores around a vertical axis of descent to the rotation of  
25diaspores with a corresponding increase in lateral motion. Diaspores were observed to stop and start rotating  
26during free fall and even reverse their direction of rotation. Fluctuations in terminal velocity (Appendix 2)  
27were also recorded and necessitated that the average rates of acceleration and terminal velocity had to be  
28used. The velocity difference at 1.0m between free fall in an atmosphere and free fall in a vacuum was  
29calculated at  $2.49\text{ms}^{-1}$  and the corresponding longitudinal cross sectional area of the diaspores was

3

1 approximately 0.088 mm<sup>2</sup> which gave an average cross sectional density of 0.868 gm<sup>-2</sup>. By applying the wind  
2 pressure constant it was determined that regardless of the horizontal wind strength the diaspores achieved  
3 wind speed within 0.34s which corresponds to a fall height of 0.5m (Appendix 3). The horizontal  
4 displacement of diaspores under varying release heights and wind velocities (Appendixes 4 and 5) records  
5 that an increase in wind velocity or release height shows a corresponding linear increase (Appendix 6) in the  
6 distance which diaspores are transported with distances of up to 85m for tree heights of 10m and winds of  
7 60.0km hr<sup>-1</sup>. The horizontal displacement for a wind speed of 60km hr<sup>-1</sup> corrected for initial acceleration for a  
8 wind speed of 60.0km hr<sup>-1</sup> provides a difference of 1.7m when compared with the assumption of  
9 instantaneous velocity for the same wind speed which equates to a corresponding lateral shift of the release  
10 point closer to the edge of the canopy. As the wind speed increases there is also a decrease in the angle of  
11 descent of diaspores (Appendixes 7 and 8). Overlaying the diaspore trajectories on a photo of a tree crown  
12 (Appendixes 9, 10 and 11) with a 1:1 grid shows that at a wind speed of 15.0km hr<sup>-1</sup> a diaspore would need  
13 to be positioned within 0.5m of the edge of the canopy in order to escape. If the distance is greater than that  
14 then the diaspores will descend into the canopy before they are blown clear of the canopy edge. As the wind  
15 speed increases the distance to the edge of the canopy also increases with the critical distance for a wind  
16 speed of 60.0km hr<sup>-1</sup> being approximately 1.0m. The distance of the *D. obovata* stands from the identified  
17 parent plants (Appendixes 12 and 13) indicate that diaspore dispersal for six of the eight stands at Marian  
18 Wood Nature Reserve occurred with wind speeds of between 30.0km hr<sup>-1</sup> and 51.0km hr<sup>-1</sup>, one stand was  
19 consistent with a wind speed of 9.0km hr<sup>-1</sup> and the shape of the 2018 stand at site 1C was consistent with  
20 wind speeds varying between 24.0km hr<sup>-1</sup> and 92.0km hr<sup>-1</sup>. Although theoretical wind speeds were used for  
21 the development of the wind dispersal model, wind speeds at Marian Wood Nature Reserve during a storm  
22 event on the 17<sup>th</sup> October 2017 were measured with a Kestrel hand held anemometer serial No. 2278445 and  
23 reached 89km hr<sup>-1</sup> (Appendix 16).

24

#### 25 Testing for secondary seed dispersal.

26 A single episode of foraging of the diaspores in the seed baskets was recorded from the 2<sup>nd</sup> May 2017 to the  
27 5<sup>th</sup> May 2017. During this time period the diaspores were actively harvested by an unidentified species of  
28 harvester termite (Appendix 13). No other incidents of foraging or removal of diaspores from the baskets  
29 was recorded.

### 13.4.2 Mapping of the establishment of individual stands of *D. obovata* and comparison against the historic GIS data

3Cutting and removal of the aerial portions of the *D. obovata* plants during the initial survey and mapping  
4exercise at survey sites 1C and 2A at Marian Wood nature Reserve (appendix 14), revealed that what was  
5originally considered to be a single stand covering most of site 1C was actually four separate stands of plants  
6(Appendix 15). At site 1C a single potential adult *D. obovata* plant was identified scrambling through the  
7forest canopy on the South side of the stand (Appendix 17). At site 2A a single potential parent plant was  
8identified growing in the canopy of a large *Ficus natalensis* to the North of the stand (Appendix 16). It was  
9also noted during this exercise that no other plant species were recorded in stands where *D. obovata* canopies  
10had achieved 100% canopy cover. Comparison of the GIS map of the positions of plants recorded at sites 1C  
11and 2A against the available historic ortho photos from 1999 to 2015 allowed the sequence of the  
12establishment of *D. obovata* stands to be identified and recorded (Appendices 15, 16 and 17). At site 1C  
13(Appendix 15 and 17) *D. obovata* successfully established in the grassland in 2002, 2006 and 2018.  
14Successful establishments at site 2A (Appendix 16 and 17) took place in 2003, 2008 and 2015. Following the  
15cutting and treatment of the identified probable parent plants at site 1C in 2012 and at site 2A in 2015 there  
16were no further recruitments of *D. obovata* into the grasslands until a new stand of seedlings was recorded at  
17site 1C in 2018. On investigation a new *D. obovata* vine was identified on the edge of the forest canopy at  
18site 1C close to where the original parent plant was treated in 2012. This plant was surveyed and was found  
19to be on the same North East and South West predominant wind line for the new stand of plants at site 1C  
20(Appendix 15 and 17). Rates of expansion of *D. obovata* stands once established (Appendix 18) showed an  
21average increase in stand diameter of 2.5m per year and it was also recorded that controlled grassland burns  
22were conducted from 2002 to 2015 (Appendix 18). No trace of the plants visible in the new stand at site 2A  
23in the 2008 ortho photo was found during the field survey and mapping exercise in 2012.

24

25The excavation of the roots of *D. obovata* plants in site 1C and 2A revealed that the plants within distinct  
26stands were connected to the same root network which formed a radial branched structure which connected  
27to a single central plant (Appendices 19 and 20). The central plants of each stand corresponded to the first  
28plant visible in each stand in the chronological sequence of ortho photos. Rooting of lateral branches was not  
29observed at Marian Wood Nature Reserve but it was recorded during the *D. obovata* survey at the Treasure

1  
2

1 Beach Grasslands Reserve in September 2018 (Appendixes 22, 22, 23 and 24) where the radial lateral  
2 branches growing along the ground were measured at an average of 6.6m with the longest recorded as 10.2m  
3 with a diameter of 16.2m at its widest point and covered an area of 132m<sup>2</sup>. This plant was not recorded in the  
4 2016 survey and averaged an annual radial expansion of 4.0m per year.

5

### 6 3.5 Discussion

7 The results of the *D. obovata* diaspore wind dispersal modelling (Appendixes 4, 5 and 6) confirmed that the  
8 horizontal displacement of diaspores was a product of wind velocity and the vertical height from which the  
9 diaspores were released. The fluctuations in the terminal velocities (Appendix 2) were attributed to the  
10 erratic rotation and helical circling of the diaspores which could have caused changes in aerodynamic  
11 buoyancy (Burrows, 1975), due to a combination of the initial angle of the diaspore relative to the vertical  
12 when released and variations in the surface structure and shape of the diaspores. The results also confirmed  
13 that the assumption of instantaneous terminal velocity and wind velocity (Appendix 6) resulted in variances  
14 in the calculation of horizontal wind displacement when the release heights were less than 0.5m (Appendix  
15 4) and changed the calculated distance back from the edge of the canopy at which diaspores could be  
16 released and effectively escape the forest fringe without falling into the canopy of the host trees. This  
17 distance was determined by a combination of canopy shapes and wind strengths which caused a change in  
18 the angle of descent of the diaspores. As wind velocities decreased (Appendixes 7, 8, 9, 10 and 11) the critical  
19 release point of diaspores moved closer to the edge of the canopy and for wind speeds below 15.0km hr<sup>-1</sup>,  
20 plants needed to be positioned on the edge of the host trees canopy to allow effective diaspore dispersal. The  
21 ballistics table (Appendix 5) also confirmed that once diaspores escape the canopy they could be transported  
22 distances of up to 80m into the grasslands by strong winds.

23

24 The single episode of foraging on diaspores by termites was not repeated and provided insufficient data to  
25 indicate if it was secondary seed dispersal or opportunistic seed predation.

26

27 The mapping of plants at site 1C and 2A at Marian Wood Nature Reserve and the Treasure Beach Grasslands  
28 Reserve and comparison with historical ortho photos showed that successful establishments of *D. obovata* in  
29 the grasslands in relation to any particular parent plant in the forest canopy is an infrequent event. However

Once *D. obovata* does become established it is capable of spreading at a continuous rate and is not controlled through the application of planned grassland burns. At site 2A there were three events over a 12 year period of which only one was confirmed by the field survey. At site 1C five separate stands were established over a sixteen year period. The tagging and mapping of individual plants in 2012 ensured that survivors of the herbicide applications could be correctly differentiated from newly germinated plants. The available information pertaining to the germination of *D. obovata* seed in a nursery (Nichols, 2017) suggests that *D. obovata* seeds do not remain viable for extended periods in the field and new plants recorded at intervals varying from three to six years after the herbicide applications were completed were unlikely to have been from seed that had lain dormant in the soil. They were more likely to have been released from the parent plant at site 2A that was broken during the 2012 storm and which subsequently regenerated and from the new parent plant identified at site 1C in 2018. Air borne diaspores move according to the wind direction when in flight (Burrows, 1975) and will gravitate to the ground along the path of the wind flow. The lack of subsequent establishments along the predominant wind lines between the forest canopy and survey sites after the parent plants were treated with herbicide at site 1C in 2012 and at site 2A in 2015 suggests that these plants were correctly identified as the source of the diaspores from which the stands were established (Appendixes 15, 17 and 18) and supports the assumption that *D. obovata* diaspores are wind dispersed.

22  
23  
24

The excavation of the *D. obovata* roots at Marian Wood NR and the identification of rooting from lateral branches recorded at the Treasure Beach Grassland Reserve confirmed that *D. obovata* spread via clonal propagation following successful establishment within the grasslands. This suggests that all of the plants comprising the individual stands mapped at Marian Wood NR and Treasure Beach Grasslands Reserve were in fact genetically identical aerial portions of single plants. This then explained how *D. obovata* can form large dense continuously expanding stands within the grasslands without any evidence of canopy contact mortality taking place.

25

26

27

28

29

3

### 13.6 Conclusions

3The results of the calculation of basic ballistics data for *D. obovata* diaspores and the comparison against  
4stands of plants surveyed in the field supports the assumption that *D. obovata* dispersal is anaemochoric and  
5that the distance at which diaspores are dispersed depends on the site specific combinations of prevailing  
6wind speeds and the height of the plant in the host trees canopy. The successful dispersal of the diaspores  
7beyond the forest boundary for an average range of wind speeds into adjacent grasslands is also dependent  
8on the diaspores being released from a position not greater than 1.5m from the edge of the host trees canopy  
9and that this critical release point shifts closer to the canopy edge as wind speeds decrease. The field survey  
10records also showed that once *D. obovata* was successfully established in a grassland the plants were  
11resilient to grassland fires, that the stand exhibited a constant rate of lateral expansion and that the primary  
12method for expansion was clonal propagation from the roots and rooting of lateral branches. The  
13confirmation of clonal propagation explained the lack of evidence of canopy contact mortality or self-  
14thinning within large dense stands of *D. obovata* and which also enabled it to establish large constantly  
15expanding stands which excluded other plant species. The implication is that although establishment of *D.*  
16*obovata* stands in the grasslands from any single parent plant is an infrequent event, once established there is  
17a continuous increase in encroachment which has the potential to transform the botanically rich moist coast  
18grasslands within the urban nature reserves of Ethekewini Municipality into mono species stands of *D.*  
19*obovata*.

## 1Chapter 4: Discussion and conclusions

### 34.1 Discussion

4The encroachment of moist coast grasslands by *D. obovata* was identified as a threat to this habitat within the  
5Thekwini Municipal area. Searches of available literature identified encroachment of grasslands by woody  
6plant species (Chapter 1 and Chapter 2) as a worldwide phenomenon (Naito and Cairns, 2011). The primary  
7driver associated with the global increase in bush encroachment was identified as the increase in atmospheric  
8CO<sub>2</sub> (Wigley et al., 2009, Battipaglia et al., 2013) but that this was either moderated or aggravated at a local  
9level by other factors such as mean annual precipitation (Devine et al., 2017), fire regimes (Higgins et al.,  
102000, Bock et al., 2007), the management of IAPs (Archer and Predick, 2014) and the presence or absence of  
11large herbivores which may result in overgrazing (Ansley et al., 2006, Ward, 2010). It was noted that the  
12woody plant species commonly cited in studies of bush encroachment were self-supporting trees or bushes  
13and no records were found of encroachment of grasslands by lianas or climbing plants (De Kler, 2004. Bond  
14and Midgley, 2012, Su et al., 2015).

16Competition between grasses and seedlings of woody plants for resources has been cited as a limiting factor  
17for the recruitment of seedlings into the adult tree populations in grasslands (Ward, 2010). Although *D.*  
18*obovata* seedlings would have to compete directly with grasses for resources this is not the case for ramets  
19produced from the lateral roots or the rooting of lateral branches of plants using clonal propagation  
20of (Fahrig et al., 1994). The clonal propagation of *D. obovata* was confirmed by the mapping of plant roots  
21and lateral branches of *D. obovata* stands (Chapter 3). New immature shoots are able to access the carbon  
22and nutrient resources of the entire plant (Oborny et al., 2000) with its developed photosynthetic capacity  
23and can therefore invest in vertical growth through the grass canopy. Once the shoots are clear of the grass  
24canopy and are no longer shaded they are then able to add to the photosynthetic capacity of the entire  
25physiologically integrated genet (Hartnett and Bazzaz, 1983). It has also been noted that C<sub>3</sub> trees growing  
26under conditions of elevated CO<sub>2</sub> are also able to increase the allocation of carbon storage to their roots  
27(Curtis and Wang, 1998, Bond and Midgley, 2012), which allows for an increased availability of stored  
28resources for the regeneration of photosynthetic capacity after fires and that, “Frequent surface fires in  
29savannas select for woody plants with underground storage organs, or clonally spreading root systems, which

1  
2  
3 promote rapid post-burn recovery” (Bond and Midgley, 2012).

4  
5 The resistance of *D. obovata* to fire was noted from the available reserve management records and that the  
6 stands mapped at Marian Wood Nature Reserve continued to expand following the implementation of  
7 controlled annual burns (Chapter 3). This was supported by the results of the Chi-square tests (Chapter 2)  
8 which confirmed that there is no relationship between fire regimes and *D. obovata* encroachment. The PCA  
9 did however confirm that there was also a weak correlation between the use of back fires versus head fires  
10 (Chapter 2). The use of back fires are associated with the depression of the post burn regrowth of grasses  
11 which compete with *D. obovata*, whereas head fires are associated with hotter burns which which results in a  
12 greater kill of woody vegetation top stems (Trollope and Trollope, 2010). Generally the results of the Chi-  
13 square tests and PCA showed that *D. obovata* was not effectively controlled through historic bush  
14 encroachment management practices. On the other hand it was noted in (Chapter 3) that at survey site 2A the  
15 application of 5% picloram as a cut stump treatment resulted in a 100% mortality of all treated plants. The  
16 presence of short stunted *D. obovata* plants on the edge of forests and bush clumps which conformed to the  
17 general description of Gullivers were recorded at New Germany Nature Reserve and Roosefontein Nature  
18 Reserve (Chapter 2). The ability of *D. obovata* to propagate clonally and the increased capacity for clonal C3  
19 plants to store carbon reserves in their roots in the presence of increased atmospheric CO<sub>2</sub> would then also  
20 increase the rates of post burn recovery after fires and enable “Gullivers” to grow beyond the top kill zone,  
21 escape the fire trap and be recruited into the adult population (Battipaglia 2012,. Girardin et al 2016,).

22  
23 The relationship between the absence of large herbivores in the grasslands and encroachment by *D. obovata*  
24 was confirmed by both the Chi-square tests and the PCA (Chapter 2). Exactly how large herbivores notably  
25 mixed feeders prevented *D. obovata* from encroaching into the grasslands where they were present is not  
26 understood. Whether or not the presence or absence of large herbivores was part of an active management  
27 strategy of the study areas, they were a component of the grassland ecosystem in which *D. obovata* was  
28 being studied. Similar relationships between mixed feeder herbivores, including impala, and the suppression  
29 or reduction of woody plant species in grasslands has been recorded globally (Roques et al., 2001, Maher et  
30 al., 2010, Su et al., 2015, Sankaran et al., 2013, Cornelissen et al., 2014). More recently the impact of mule  
31 deer on the recovery of clonally reproducing *Populus tremuloides* (Rogers and McAvoy, 2018) by over

1  
2  
3browsing on adventitious shoots which suppressed the growth of new saplings has been reported. It is  
4suggested that a similar relationship may exist between *D. obovata* and mixed feeders such as the domestic  
5goats and impala recorded in the grasslands where *D. obovata* was absent, in that browsing on *D. obovata*  
6seedlings may reduce their capacity to successfully compete with grasses for available resources and be  
7recruited into the adult population. This relationship does however require further investigation.

8  
9There are key differences between the physiology and development of lianas and self supporting woody  
10plants, the most significant of which is the lack of a self-supporting stem which requires the investment of  
11carbon resources in the form of sclerenchyma and lignin. Lianas can therefore invest in the production of  
12secondary cambium (Rowe and Speck, 2005, Isnard and Silk, 2009), which increases the hydraulic capacity  
13of the stems and available leaf area for photosynthesis in relation to their stem ratio. It was also noted that  
14during growth the vertical juvenile stems of lianoids tended to be stiff and the development of a flexible stem  
15did not occur unless the stems came into contact with the trunk or branches of a host tree and did not reach  
16maturity (Lahaye et al., 2005)). The acquisition of the climbing trait has occurred independently in several  
17plant clades through the acquisition of genes which permanently and irreversibly suppressed the formation of  
18self-supporting trunks. The implication is that lianas including *D. obovata* are dependent on a forest habitat  
19and are not evolved to compete in a grassland environment. Conversely, it can be reasoned that in the  
20absence of contact with trees or bushes, the juvenile stems will remain stiff or semi flexible and it is recorded  
21that *D. obovata* can form bushes of several metres in height (Coates Palgrave, 1977).

22  
23Besides the confirmation of the dispersal of *D. obovata* diaspores by wind (Chapter 3) two other aspects of  
24lianoid propagation were confirmed by the mapping of individual plants in large dense stands in the two  
25urban nature reserves. These were the clonal reproduction of plants from the rooting of lateral branches or  
26runners in contact with the soil and the production of adventitious shoots or suckers from shallow lateral  
27roots. It has been noted that although individual genets of clonally reproducing plants follow the  $^{-2/3}$  self  
28thinning rule, it does not apply to physiologically integrated ramets of the same plant (Hartnett and Bazzaz,  
291983). This then provided an explanation for the ability of *D. obovata* to form large dense stands which  
30effectively exclude other plant species.

31

1The results of the wind dispersal modelling and history of establishments indicates that although long  
2distance diaspore dispersal is possible, the successful establishments at the two survey sites at Marian Wood  
3Nature Reserve were infrequent and occurred at an average rate of one establishment every 5.6 years. This  
4could indicate that *D. obovata* seeds have a very low germination rate in the grasslands or that the seedlings  
5may not be able to compete very well against grass species especially where a closed grass canopy is present  
6(D'Onofrio et al., 2015). The wind dispersal model (Chapter 3) is simplistic and was developed for the  
7primary purpose of confirming if there was a critical maximum distance from the edge of the canopy in order  
8for successful diaspore dispersal to take place. It was estimated that this distance was 1.5m but varied  
9according to a combination of the gradient and shape of the canopy and wind strengths. The model does not  
10account for the effects of wind turbulence, vortex shedding and storm events (Cain et al., 2000, Nathan et al.,  
112002, Soons., et al., 2004, Tackenberg et al., 2003), which can greatly extend the range of seed dispersal and  
12explains the presence of *D. obovata* recorded throughout the grasslands in some of the study areas (Chapter  
132) which were further than 100m from the forest. The percentage of *D. obovata plants* situated within 1.5m  
14of the edge of the canopy was not assessed as part of this study and an estimation of the annual number of  
15establishments for any given length of the forest canopy was not performed. However the mapping of *D.*  
16*obovata* distribution in four nature reserves (Chapter 2) did record very high densities of *D. obovata* in the  
17forest canopies between 1:64m<sup>2</sup> – 1:400m<sup>2</sup> in the centre of the forests to 1:16m<sup>2</sup> – 1:64m<sup>2</sup> on the forest  
18fringes (Chapter 2) and the frequency of *D. obovata* mapped on the fringes of the forests in Roosefontein  
19Nature Reserve and the Westville Campus grasslands suggests that successful establishments have occurred  
20on numerous occasions during the time period for which historical GIS data was available.

21

#### 224.2 Conclusion

23It was confirmed that *D. obovata* is primarily distributed through wind dispersed diaspores and that in order  
24to successfully disperse beyond the forest boundaries into adjacent grasslands *D. obovata* diaspores needed  
25to be released from a position close to the canopy edge the exact distance depending on a combination of  
26canopy shape and wind strengths. *D. obovata* establishments within the grasslands were infrequent in  
27relation to any particular parent plant and could be attributed to competition for resources between seedlings  
28and grasses. Once *D. obovata* plants were successfully established in the grasslands the plants had an  
29inherent competitive advantage over grass species through clonal propagation of adventitious roots and

rooting of lateral branches which enable the plant to expand its canopy area at a continuous rate. The process of self thinning through canopy contact mortality was avoided since all plants within any single stand were in fact ramets of a single plant. Once established in the grasslands *D. obovata* was not effectively controlled through historic bush encroachment management practices and only the manual clearing and treatment with a herbicide was successful. A correlation between large herbivores and the lack of *D. obovata* was identified but the relationship is not understood. Finally, *D. obovata* could no longer be considered as occurring in only forest or woodland habitats and in the absence of large herbivores has successfully encroached into the moist coast grasslands of the reserves of eThekweni Municipality and represents a further threat to this already threatened grassland habitat.

#### 14.3 Challenges and future research requirements

A number of shortcomings were identified in the understanding of *D. obovata* and its encroachment into moist coast grasslands and which would benefit from further investigation. The first is that the phenology of *D. obovata* is unknown and the plant seems to have been taken for granted as just being part of the forest habitat despite it occupying a large portion of that habitat. The second is that the notion that plants that have evolved to occupy specialist niches and are restricted to the habitat or environment in which they have evolved has been challenged. This raises a question regarding the potential for plants previously considered as specialised to use the traits that provide them with a competitive advantage in their preferred habitat to exploit available opportunities in modified ecosystems such as fragmented landscapes where new niches are provided or alternatively where competition for resources or agents that suppress their germination or growth have become absent. The third shortcoming is the lack of information pertaining to the germination rates of *D. obovata* seed in the field and what conditions are required for successful germination to occur. The final question that requires further investigation is the relationship between *D. obovata* and large mixed feeder herbivores where the actual mechanism for the suppression of *D. obovata* has not yet been identified. Whether or not mixed feeders suppress the ability of *D. obovata* to compete against grasses at the seedling stage or if they forage on adult plants is unknown. This needs to be confirmed together with the stocking ratios required to control *D. obovata* in the grasslands for the effective management of threatened moist coast grasslands by reserve managers.
